ACKNOWLEDGMENTS

To accomplish this task, I am deeply indebted to Dr. Oldham, the chairman of my committee. His expertise, encouragement, guidance, and patience have supported me throughout the process and will never be forgotten.

My sincere gratitude is also expressed to Dr. Marcy and Dr. Gustafson for their support. Special thanks go to Mrs. Weiner for her help in the various phases of this research as well as in my academic years in the Computer Science Department.

Finally, I would like to thank my parents and my husband, Yung-Hui, for their support throughout the study.

ABSTRACT

Two neural network models, Model H-H1 (Hogg and Huberman, 1984) and Model H-H2 (Hogg and Huberman, 1985) have been successfully applied to the font recognition problem and were used to recognize 26 English capital letters, each with six font representations. Recognition rate, memory space requirement, learning speed, and recognition speed were used to measure the models' performances. Model parameters such as memory array size, S_{min_Smax} , and M_{min_Mmax} were varied to elucidate the models' behavior.

As a result, both models achieved a 100% recognition rate when all six fonts were used as the training as well as the recognition set. When three out of six fonts were used for training, Model H-H1 achieved a maximum recognition rate of 87.82% and Model H-H2 achieved a maximum recognition rate of 89.10%. This shows that the basins of attractor states existed for the letters in most of the various font presentations. Model H-H2 significantly outperformed Model H-H1 in terms of recognition rate, use of memory space, and learning speed when all six fonts were used as the training set. This was supported by the results of the Pairwise T Test.

CHAPTER I

INTRODUCTION

Scope

Artificial Neural Net systems (ANS) is a rapidly growing research area because of its promise to solve problems that have confounded computer science and artificial intelligence for over 30 years (Hecht-Nielsen, 1987). Primarily, ANS technology is being applied to the development of information processing systems which perform tasks similar to those that the human brain does. For example, ANS technology has enhanced the processing capabilities of high-performance pattern recognition process.

In the past, many pattern recognition problems have not been solved successfully. Although many traditional computer science approaches have been applied, methods for carrying them out affordably with sufficient speed and with adequate robustness have not been available (Hecht-Nielsen, 1987). Artificial neural net models are an alternative which employs massive parallelism to complete the job in a reasonable time. One of the major reasons that artificial neural nets out-perform other approaches in solving the recognition problem is that the structures of the models are developed based on the understanding of the biological

nervous system (McClelland, Rumelhart, and Hinton, 1987). Other ANS properties include the following:

(1) The existence of attractor states: An attractor state is the state of a system that is at least quasi-stable (Oldham, 1986). It has been proven that attractor states exist in discrete systems such as computer models (Hogg and Huberman, 1985). This is an important feature since the attractor states can be used to store information. The information is introduced into the attractor by training the system using examples. Moreover, computing with attractive fixed points can lead to reliable behavior (Hogg and Huberman, 1984). This feature makes the neural net more attractive to the pattern recognition application.

(2) A learning and recognition capability: Learning and recognition are the basic processes involved in pattern recognition. Some artificial neural networks, such as the Hogg and Huberman models, can be trained by repeatedly presenting example patterns from an environment. The elements of the memory matrix which represents the model are adjusted accordingly in discrete time steps until the system converges according to some criteria. The system is said to be trained or to have converged if the values of the memory matrix reach stable values. If the system is properly trained, it will then recognize a pattern with which it was trained.

(3) A fault tolerant capability: Because of the existence of attractor states, the overall performance of the system tends to be insensitive to partial internal failures or input data errors. This is because the learned states are attractor states and the system is capable of evolving to the attractor states based on only partial or approximate information.

(4) High performance speed: The massive parallelism (parallel input channels and parallel output channels) enables the system to process with satisfactory speed. As mentioned previously, pattern recognition involves the learning and the recognition phases. In the learning phase, the time complexity depends on the number of iterations before the system converges; in the recognition phase, the time is independent of the code complexity.

(5) VLSI implementation: The structure of the network makes it easy to implement in VLSI technology.

In this research, the modeling of neural networks was studied and their capabilities in pattern recognition were explored. The study has made a substantial contribution to the understanding of neural networks through the application of the model to the area of pattern recognition.

Problem Definition

From among the various neural net models, two models that were developed by Hogg and Huberman in 1984 and 1985

(Model H-H1 and Model H-H2) were chosen as the focus of this study. They were examined, elucidated, and evaluated when applied to font recognition. Basically, Model H-H1 and Model H-H2 are fairly simple and easy to implement. Properties that make these models interesting are:

(1) The models are quite simple in presentation and can be easily implemented in software.

(2) Some non-determinism is injected via the memory update.

(3) All calculations can be done in parallel as a pipeline.

(4) Since the input and output contact the external world at the edges of the system, the models can be easily implemented by VLSI technology (Oldham, 1986).

(5) Although the topologies of these two models are the same, their output functions and learning rules are different.

The behavior of Model H-H1 has been investigated by several studies. These studies revealed that this model has a self-repairing capability (Hogg and Huberman, 1984) and conditional learning capability (Hogg and Huberman, 1985).

Model H-H2 can dynamically modify the basins of attractions to include or exclude a particular set of inputs by using the coalescence process or the dissociation process. The coalescence process is used to produce the

same outputs when the corresponding inputs are originally associated with different outputs; the dissociation process is used to differentiate the outputs when the input are initially mapping into the same outputs. To be able to manipulate the basins of attractors of the model is a very desirable feature in recognition application.

The basins of attractions of Model H-H2 can be manipulated to couple the desired grouping of inputs into specific outputs. This feature is particularly useful in the area of font recognition (Hogg and Huberman, 1985). In summary, the study was conducted to better understand, elucidate, and evaluate the models developed by Hogg and Huberman. The goals were accomplished by applying the models to font recognition.

Specific Tasks

The study was accomplished by the following steps:

(1) Problem formulation: Each English letter has many font representations. Although each font differs from the others, their overall images should be treated the same. In the study, the models were used to recognize the English characters independent of their font representations.

(2) Software Development: To simulate the behavior of these models, programs were developed in PL/I and were executed on a VAX 8650.

(3) Encoding scheme development: To obtain reliable recognition, an encoding system was developed and the attributes of the English characters were derived. Six fonts for each of the 26 English capital letters (156 characters in total) were encoded.

(4) Application of models through simulation: Half of the codes (the training set) were submitted to each model during the training phase. After each model was trained, the testing set was presented to it and the behavior of the model was recorded. The testing set consisted of all 156 characters. To explore the behavior of the models, their parameters were varied and different simulation data were generated.

(5) Model comparisons: The performance of these models were determined by comparing their recognition rates, memory space requirements, learning speeds, and recognition speeds. Also, the performances of the models were compared with the results of Cash and Hatamian's study (1987) and the result of Fujii and Morita's study(1971).

CHAPTER II
BACKGROUND INFORMATION AND
LITERATURE REVIEW

In this Literature Review, the first section provides a review of the basic structures and functions of an Artificial Neural System (ANS). The second section introduces various neural net models. The Hogg and Huberman models which are the focus of this study are illustrated in the third section and was followed by a summary.

Neural Network Model

ANS Description

An artificial neural network is a network that consists of a set of nodes, the interconnections among nodes, learning rules, and input/output data (Oldham, 1986). The nodes, also called neurons or processing elements (PEs), represent particular conceptual objects and perform relatively simple computational processes. A node's job is to receive inputs from its neighbors, to compute the output according to the computation rules, and to send the output value to its neighbors. Thus, each node has little information stored internally and works as a short term working memory (Fahlman and Hinton, 1987).

Each node is connected to one or more other node(s) via an interconnection weight. In general, the connection weight can be positive or negative. Positive weights are excitatory; negative weights are inhibitory. The weights are modified as a function of experience by the adaptive or learning rules and the information is stored in the connectivity pattern. In other words, the connection weights determine the long term storage of information (Fahlman and Hinton, 1987). Figure 1 illustrates the architecture of a typical ANS (Oldham, 1986).

As previously mentioned, changing the knowledge stored in the network involves modifying the pattern of connectivity and the weights. Many, but not all, learning rules can be considered as the variation of the Hebbian learning rule developed in 1949 (McClelland, Rumelhart, and Hinton, 1986). The basic principle for the Hebbian rule is that, if a pair of neighboring nodes are both highly active, the weight between them should be strengthened.

Overall inputs and outputs take place at the edges of the network. The inputs for a node are the outputs of its neighboring nodes. Similarly, the output from a node is input for other nodes.

Features of ANS

Artificial neural net models are parallel, distributed process models. They are inherently parallel since a large

Figure 1: The Architecture of
a Typical ANS

number of the process elements perform their computations simultaneously and independently. They are inherently distributed because each process element is assigned a very tiny sub-task and stores little information.

The distributed feature enables the artificial neural net to be fault tolerant in regards to both internal failures and input data errors. This feature is drawn from the cognitive research idea that a given neuron is involved in many processes and many neurons participate in many decisions or processes (Oldham, 1986). As a result, a given neuron may play an insignificant role in the entire storage process. Consequently, a degree of fault tolerance is achieved by the process.

The parallel feature provides the models with computational efficiency because that all neurons perform simple operations, and a large number of operations occur concurrently.

Mathematical Model of ANS

Symbolically, a neural net can be viewed as $G(I, O, n, f(n), C)$. Where I is input, O is output, $f(n)$ is function operating at the n th node, and C is a connectivity matrix. The function f can be either linear or non-linear. Linear models have limitations because they can not mix or combine basic states to generate new states that correspond to learning or creativity (Oldham, 1986). They can only

accomplish superficial mixing of learning. Therefore, non-linear models were studied in this research.

Non-linear models are difficult to analyze. Even the simplest non-linear mechanism with very few nodes, is extremely complicated and intractable. Currently, the only method of analysis is accomplished by computer simulation (Oldham, 1986).

The most frequently used non-linearity functions are describe mathematically below:

(1) hard limiter: $f(x) = -1, \text{ if } x < 0$
 $f(x) = 1, \text{ if } x > 0$

(2) threshold logic element:

$$f(x) = 0, \text{ if } x < 0$$

$$f(x) = x, \text{ if } 0 < x < c$$

$$f(x) = a, \text{ if } x > c$$

where c is the threshold

and a is a constant

(3) sigmoidal non-linearity: $f(x) = 1 + \tanh(x)$

Figure 2 presents these non-linearity functions graphically (Lippmann, 1987).

Applications of ANS

Neural net models have been applied to the following problem areas:

Figure 2: The Non-linearity Functions

(1) Classifier: Determining which one of M classes is the most representative of an unknown input pattern.

(Lippmann, 1987). Neural net models can identify which class best represent a input pattern. This is a classical decision theory problem.

(2) Pattern Associator: The goal of pattern association is to build up an association between patterns defined in one set and patterns defined in another set. After the connections between sets are established, the associated pattern will appear on the second set if a particular pattern reappears on the first set (Lippmann, 1987). An auto-associator is one such that the output pattern is associated with the same as the input. Thus, whenever a portion of the input pattern is presented, the remainder of the pattern is to be filled in or completed. The content-addressable memory (also called associative memory) that can recall total storage information based on partial or noisy input is an example of auto-associator. A hetero-associator is one in which a pattern in the first set is associated with a different pattern in the second set.

(3) Regularity Discovery (feature detector): The models learn to respond to "interesting" pattern in their inputs (McClelland, Rumelhart and Hinton, 1987) and will divide the N input patterns into M classes.

Various Neural Network Models

An ANS is specified by the net topology, node characteristics, and training or learning rules (Lippmann, 1987). As mentioned previously, the pattern recognition process involves a training phase and a recognition phase. In the training phase, some models are trained with supervision while others are not. When a model is trained with supervision, it is provided the side information or label that specifies the correct class for the new input patterns. Whereas, nets trained without supervision, no information concerning the correct class is provided. Among those models that are trained with supervision, Hopfield models were used as auto-associators while the Perceptron and Anderson models were used as hetero-associators. Among those models that are trained without supervision, the Carpenter and Grossberg model was used as an auto-associator and the Hogg and Huberman models were used as hetero-associators. Figure 3 presents the model classifications.

Hopfield Models

The various Hopfield models, which are highly connected with strong feedback, can be used as an associative memory or can be used to solve optimization problems. In the models that can be used as associative memories, the inputs and outputs are binary values which can take on +1 or -1.

Figure 3: Model Classifications

The output of each node is fed back to all other nodes via weights. Since the model is trained with supervision, exemplars are provided. Following the initialization, the net iterates in discrete time steps. The pattern specified by the node outputs, after convergence, is the net output. It has been proven that this net converges to stable final states when the weights are symmetric (Hopfield, 1982). This model has two major disadvantages when use as a content addressable memory. First, there is a limitation in the number of patterns that can be stored and accurately recalled. Second, the exemplar pattern is unstable if it shares many bits in common with another exemplar pattern.

Also, Hopfield models can solve optimization problems such as the classical Traveling-Salesman problem, analog to digital conversion problems, and linear programming problems. The stable states of the network containing N neurons are the local minima of the energy function E and the circuit operates over the interior of a hypercube defined by the input patterns. The minima only occur at the corners of the hypercube; stable states correspond to the 2^N corners of the hypercube that minimizes E . These optimization problems can be solved by the following steps: (1) Choosing the connectivities; (2) Choosing the input bias circuits, which appropriately represent the function to be minimized; (3) Providing an initial set of inputs that cause the system to converge to a stable state which represents

the minimum of the function; (4) Interpreting the solution from the stable final state (Hopfield and Tank, 1985).

Carpenter and Grossberg Models

Carpenter and Grossberg introduced the adaptive resonance theory (ART) which forms clusters and is trained without supervision (Lippmann, 1987). ART embedded a competitive learning model into a system that can solve the stability-plasticity dilemma (Carpenter and Grossberg, 1988). Stability is essential for the system to remain unchanged in response to irrelevant events. Whereas plasticity is essential for the system to learn in response to significant new events. The stability-plasticity dilemma says that the system must employ some mechanism to distinguish between signal inputs and noisy inputs so that it knows how to switch between its stable and its plastic modes.

The ART I deals with binary inputs, while ART II deals with analog inputs. These two models are rather complicated and involve many parameters and learning rules. Among these parameters, the vigilance parameter, which ranges between 0.0 and 1.0, determines how close a new input pattern must be to a stored exemplar to be considered similar. High vigilance forces the system to search for new categories in response to small differences between input and expectation.

Thus the system classifies input patterns into a large number of categories. On the other hand, low vigilance enables the system to tolerate large mismatches and thus groups input patterns into a small number of categories. It has been mathematically proven that an ART I architecture is capable of stably learning a recognition code in response to an arbitrary sequence of binary input patterns, until it utilizes its full memory capacity (Carpenter and Grossberg, 1987).

Single Layer Perceptron

The original perceptron was developed by Rosenblatt (Lippmann, 1987). Perceptrons are able to decide whether an input belongs to one of two classes (Class A or Class B) that are separated by a decision region created in the multidimensional space spanned by the input variables. The basic idea is to compute a weighted sum of input elements, subtract a threshold, and pass the result through a hard limiting non-linearity function such that the output is either +1 or -1. In the training phase, both inputs and desired outputs are provided. The connection weights are adapted only when the actual output differs from the desired output. The decision rule is to respond Class A if the output is +1 and Class B if the output is -1. The Perceptron forms two decision regions separated by a hyperplane.

Single layer perceptrons can be expanded to multi-layer perceptron by introducing hidden layers. A three-layer perceptron can form arbitrarily complex decision regions. Although it can not be proven that this model will converge, it has been shown to be successful for many problems of interest.

Anderson Model

The Brain In a Box (Anderson model) was developed by Anderson in 1977. This model performs as a simple linear associator that is trained with supervision. In the model, any unit can be connected to any other unit.

Assume that there are two groups of N neurons, X and Y and every neuron in X projects to every neuron in Y . A synaptic strength, a_{ij} , connects the j th neuron in X with the i th neuron in Y . Let f_1 be a vector that represents X and g_1 be a vector that represents Y . An association can be made between f_1 and g_1 so that the presentation of f_1 alone will give rise to g_1 . This association is developed by

$$A_1 * f_1 = g_1 \quad \text{where } A_1 \text{ is the connectivity matrix.}$$

A_1 can be computed by

$$A_1 = g_1 * f_1^T.$$

When there are k sets of neurons, namely (f_1, g_1) , $(f_2, g_2), \dots, (f_k, g_k)$, there exists a single connectivity

matrix to associate the set of activity patterns. Each pair of neurons can generate a connectivity matrix, A_i . Then the overall connectivity matrix A can be computed by

$$A = \sum A_i.$$

It has been mathematically proven that, if the input vectors are mutually orthogonal, the system can perform the association perfectly (Anderson, Silverstein, Ritz, and Jones, 1977).

Hogg and Huberman Models

Hogg and Huberman models, which are flow forward and synchronous networks, were developed in 1984 and 1985. They will be referred to as Model H-H1 and Model H-H2, respectively. The models are able to map many inputs to a few final states. The final states are called fixed point attractors. The set of inputs that map into a given output defines the basin of the attractor for that output.

The architectures of Model H-H1 and Model H-H2 are exactly the same and each can be represented by rectangular matrices (memory matrices) that consist of M rows and N columns of identical processors, each of which is locally connected to its neighbors. Each element has a value stored in it. Additionally, each processor has an adjustable internal state, or memory, which allows it to adapt to its

local environment. The overall input and output take place at the edges of the matrix, with the upper edge of the matrix (the first row) for input and the lower edge (the last row) for output. For each element, it receives two integer inputs from its neighbors along its diagonals in the preceding row and produces an integer output which in turn becomes an input to the nodes along the diagonals in the following row (see Figure 4).

The hard limiter non-linearity function is used so that the output values are constrained to lie within a range, namely $[S_{min}, S_{max}]$. The memory values are limited within $[M_{min}, M_{max}]$ range. Those output values that are equal to the extremes of these ranges are said to be saturated.

Let $IL_{ij}(k)$ and $IR_{ij}(k)$ be the inputs to the element in the i th row and the j th column after the k th time step and let $O_{ij}(k)$ be the output value for the i th row, j th column element. The connections between elements are defined by these relations.

$$IL_{ij}(k) = O_{i-1,j-1}(k),$$

$$IR_{ij}(k) = O_{i-1,j+1}(k).$$

where $1 \leq i \leq M$ and $1 \leq j \leq N$

The boundaries of the matrix, for the top, bottom, and sides edges are specified respectively as

Figure 4: The Hogg and Huberman Model

$$O_{0j}(k) = S_j(k),$$

$$O_{mj}(k) = R_j(k),$$

$$O_{i0}(k) = O_{in}(k),$$

$$O_{i,n+1}(k) = O_{i1}(k).$$

where $S(k)$ is the external input signal to the matrix at step k , and $R(k)$ is the resulting output vector.

The two models employ different output functions and learning rules which are described next.

(1) Model H-H1:

(A) The output from each element for the $k+1$ step is

$$O_{ij}(k+1) = \max\{S_{\min}, \min(S_{\max}, M_{ij}(k) [IL_{ij}(k) - IR_{ij}(k)])\}.$$

This rule enhances the differences of the inputs by multiplying them by the memory value. The saturation process keeps the values within the specified interval.

(B) The memory values are updated by the following rule:

if $O_{ij}(k) > O_{i,j-1}(k)$ and $O_{ij}(k) > O_{i,j+1}(k)$ then

$$M_{ij}(k) = \max\{M_{\min}, \min(M_{\max}, M_{ij}(k-1) + 1)\}$$

else

if $O_{ij}(k) < O_{i,j-1}(k)$ and $O_{ij}(k) < O_{i,j+1}(k)$ then

$$M_{ij}(k) = \max\{M_{\min}, \min(M_{\max}, M_{ij}(k-1) - 1)\}$$

else

$$M_{ij}(k) = M_{ij}(k-1).$$

(2) Model H-H2:

(A) The output function for the second model is

$$O_{ij}(k+1) = \max(S_{\min}, \min(S_{\max}, S(IL_{ij}(k), IR_{ij}(k)) * (|IR_{ij}(k)| + |IL_{ij}(k)|) + M_{ij}(k)))$$

where for even rows, if $IL_{ij}(k)$ is zero, then $S(IL_{ij}(k), IR_{ij}(k))$ is the sign of $IR_{ij}(k)$, otherwise the sign of $IL_{ij}(k)$; and for odd rows the roles of $IL_{ij}(k)$ and $IR_{ij}(k)$ are reversed.

(B) Learning rules for the second model are:

(a) The coalescence Rule (contracting rule) is capable of dynamically associating the basins of two or more attractors to produce the same attractor.

Figure 5 pictorially demonstrates the basins of two attractors before and after the process according to the rule listed below.

if at least one of $O_{ij}(k-1)$ and $O_{ij}(k)$ is not saturated AND $O_{ij}(k) * O_{ij}(k-1) < 0$ then
change M_{ij} by 1, with the sign of the change given by the sign of the output with largest magnitude,

else

M_{ij} is unchanged.

(b) The dissociation rule (expanding rule) is used to separate the inputs which initially map into

Figure 5: Basins of Attractor Change
After the Coalescence Process

the same output. The expanding rule operates opposite to the contracting rule.

if at least one of $O_{ij}(k-1)$ and $O_{ij}(k)$ is not saturated AND $O_{ij}(k) * O_{ij}(k-1) > 0$ then
change M_{ij} by 1, with the sign of the change opposite of that of either output

else

M_{ij} is unchanged.

In the training phase, a set of training patterns are submitted to the models, periodically, as a pipeline. Then the outputs and the memory values are updated according to the various rules. The model is said to be stabilized if the output values for the input patterns do not change. Once trained, the memory states will be fixed. The official outputs can be obtained by running the inputs through the model one more time. This has the effect of fixing the output patterns after the memory is locked and bars against matrix changes to the output patterns due to one or more memory element changing in the later training phase. In the recognition phase, the recognition set is sent to the model. By comparing the outputs with the official outputs, the model is capable of determining whether the input is one of the trained patterns.

Self-organizing, self-repairing and conditional learning exist in the Hogg and Huberman models. Self-

organizing means that the model is capable of converging to fixed point attractors. Self-repairing means that small fluctuations in either data or memory values won't cause the model to relax to another attractor. Conditional learning means that a set of input patterns can be learned faster if they are close to previously learned ones.

Summary

The capability of dynamically changing the basins of attractors opens a new research area. As Hogg and Huberman (1985) suggested, the coalescence and dissociation processes provide a flexible way to transform desired groupings of inputs into specific outputs. These processes are particularly useful in font recognition since the sets of inputs generated by an encoding scheme for the same letters in different fonts can be identified as an equivalent class.

Little is known about the dynamics of attractor states and their behavior under general circumstance. In fact, a whole new area of research has been initiated in this area called "chaos theory" in the last 10 years (Schuster, 1988). Issues such as the performance stability of the models when they are subjected to parameter changes, can not be answered with ease, even in the simplest nontrivial cases. Thus more research work is needed to gain insight and an understanding of the behavior of these models.

CHAPTER III

METHOD AND APPROACH

This study was conducted to understand, elucidate, and evaluate the two models developed by Hogg and Huberman (H-H1 and H-H2). These goals were accomplished by applying the two models to font recognition problem. Font recognition was achieved by following these steps: (1) Problem Formulation, (2) Software Development, (3) Encoding Scheme Development, (4) Application of Models Through Simulation, and (5) Model Comparisons.

Problem Formulation

Dynamic modification of the basins of attractors is very useful in recognition problems that require putting sets of inputs into the same equivalent classes. Thus font recognition was chosen to explore the models' recognition capabilities.

Each English letter has many font representations. Although fonts for a particular letter differ from one another, the overall images are recognized by humans as the same letter. In other words, letters in various fonts are treated as being in the equivalence class. When the models are applied to font recognition, it is desired that they

recognize letters independent of their font representations. For this study, six fonts were selected for the 26 capital letters of the English alphabet. The fonts, which included (1) Courier, (2) New York, (3) Chicago, (4) Geneva, (5) Times, and (6) Venice, were generated for each letter by a MacIntosh computer. Figure 6 lists the 156 target characters.

The goal of this study was to discover how well the models can learn and recognize the letters in various fonts. The learning phase was accomplished by submitting the training set to train the model. The training set, in this case, are the vector representations of 78 characters (3 fonts for 26 capital letters). The recognition phase was accomplished by submitting the vector representations of 156 characters (6 fonts for 26 capital letters) to determine whether the models can recognize the letters correctly.

Software Development

In order to explore the behavior of the models, programs were developed in PL/I and were executed on a VAX 8650. The programs were implemented using top-down design and step-wise refinement schemes. The program to simulate Model H-H1 contains 685 statements and is provided in Appendix A; the program to simulate Model H-H2 contains 917 statements and is provided in Appendix B. The inputs to the models, one-dimensional character vectors that represent the

Figure 6: The 156 Target Characters

target characters, will be discussed in detail in following sections.

Encoding Scheme Development

The principal difficulty encountered in the pattern recognition problem is finding a way to present the patterns in a formalized manner. In many successful character recognition systems, a character is first normalized (e.g., aligned in position), then preprocessed (e.g., by feature extraction), and then classified. In order to produce satisfactory results, a good preprocessing algorithm (encoding scheme) is needed. A good encoding scheme must be able to express the objects under consideration in a compact way, without losing any information. The steps to encode the input characters are (1) Normalizing fonts and Generating character matrices; (2) Selecting character properties and Generating property matrices; (3) Computing the Filter Matrix; and (4) Extracting Properties and Constructing Character Vectors. These steps are discussed in the following paragraphs.

Normalizing Fonts and Generating Character Matrices

A total of 156 capitalized English characters were translated into 18x18 character matrices. In the character matrices, 0s represent the background and 1s represent the

character image. The matrices are the inputs to the next process. An Example of the character 'A' in Courier font and its matrix representation are shown in Figure 7.

Selecting Character Properties and Generating Property Matrices

The inputs to models H-H1 and H-H2 are one-dimensional vector. Therefore, the character matrices (18x18) have to be transferred to vector representations. To accomplish this, 14 selected properties (Fujii and Morita, 1971) that constitute the basic building blocks of a character were extracted from each character matrix. Each property was represented by a 3x3 matrix. The selected character properties and their corresponding property matrix are shown in Figure 8. The 14 properties are extracted from each character to build a 14-tuple (the character vector C) in which c_i is associated with the i th property.

A combined property matrix (X) is a 14x9 matrix which represents the 14 selected character properties. Each row of X is a 1x9 vector (x_i) that represents a character property (see Figure 8). The nine elements in x_i are obtained by chaining the three rows of the 3x3, i th property matrix into a 1x9 vector. For example:

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \Rightarrow x_i = [1 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 1].$$

Figure 7: The Courier 'A' Font and Its Matrix Representation

Figure 8: The Selected Character Properties and Their Matrix Representations

To be specific, X is constructed by putting the vector corresponding to the first property (x_1) in the first row of X, the vector corresponding to the second property (x_2) in the second row of X, and so on. That is,

$$X = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ x_{13} \\ x_{14} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ & & & \vdots & & & & & \\ & & & \vdots & & & & & \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{bmatrix} .$$

Computing Filter Matrix

In this section, the concepts of the property recognition matrix (Y) and the filter matrix (W) will be introduced and their functions will be explained.

The property recognition matrix (Y) is a 14x9 matrix which represents a simplification of the property matrix. Matrix Y is an arbitrarily chosen matrix that is constructed as simple as possible. For example:

$$Y = \begin{bmatrix} Y_1 \\ Y_2 \\ Y_3 \\ \vdots \\ \vdots \\ Y_{13} \\ Y_{14} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ & & & \vdots & & & & & \\ & & & \vdots & & & & & \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \end{bmatrix} .$$

The filter matrix (W) is a 9x9 matrix which maps X (the combined property matrix) to Y. Their relationship is

$$Y = XW.$$

Given X and Y , W is equal to $X^{-1}Y$, if X and Y are square and non-singular matrices. In this case, X is a 14×9 rectangular matrix (there are more equations than unknown). Therefore, W is over-determined and no unique solution exists. In this project, the minimum squared error (MSE) technique was adopted (Duda and Hart, 1973) to approximate W . The MSE procedure minimizes the squared error between Y and XW . Using this procedure, the pseudoinverse of X (X^+) is computed by

$$X^+ = (X^t X)^{-1} X^t.$$

where X^t is the transpose of X and $(X^t X)^{-1}$ is the inverse of $X^t X$, thus

$$W = X^+ Y.$$

After W is computed by minimizing $(Y - XW)^2$, the exact Y is recomputed as the product of X and W .

Extracting Properties and Construct Character Vectors

Recall that each character is represented by a 18×18 character matrix. The purpose of this step is to extract the selected properties from the character matrix and to construct the character vector C . To extract character properties, let A be the search area (character matrix) and

let w be a 3×3 window matrix as shown in Figure 9. The window starts moving from the left upper corner of the search area all the way across the first three rows (rows 1, 2, and 3). It then moves down one row (rows 2, 3, and 4) and scans all the way across, and so on. Basically, the movement is made from left to right and from top to bottom. The search is stopped when the lower right corner of the window coincides with the lower right corner of the character matrix. Let z' be a 1×9 vector whose elements are obtained by chaining the 3-row elements in w . For example:

$$w = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \Rightarrow z' = [1 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 1]$$

Then z' is recognized as one of the selected properties if it maps to y' ($y' = z'w$) which is one of the rows in Y .

If z' is recognized, say $y' = y_k$, then the k th element (c_k) in the character vector is incremented by a weighting factor. The weighting factor is a function of property as well as the property location. For those properties that occur rarely, such as property cross, their location in the character matrices were identified by assigning different weights. The values of the weights are arbitrarily assigned and have no meaning other than for distinguishing purposes. To determine the weighting factor, the character matrix was divided into nine 6×6 portions with the left upper portion assigned score 1, 2 to its right and so forth (see Figure

Figure 9: The Search Matrix and the Windows

10). Table 1 lists the weighting factors. On the other hand, for those character properties that occur frequently, their location were ignored. One was assigned to every occurrence of the property no matter where it is. The character vector C is a 1×14 vector ($C = [c_1, c_2, \dots, c_{14}]$) and each element in C is an accumulated score for its corresponding property. The character vector for each character matrix is extracted according to the following algorithm:

do $i=1$ to 16 by 1

do $j=1$ to 16 by 1

$$z' = [A_{i,j} \quad A_{i,j+1} \quad A_{i,j+2} \quad A_{i+1,j} \quad A_{i+1,j+1} \quad A_{i+1,j+2} \\ A_{i+2,j} \quad A_{i+2,j+1} \quad A_{i+2,j+2}]$$

$$y' = z'W$$

if y' exactly matches one of the rows in Y , say $y' = y_k$,

then C_k is incremented by the weighting factor of the

k th property

end j

end i .

The encoding scheme is affected by the relative position of the properties. Also, the thickness of the line of the character is restricted to be one unit.

Only the sign distribution of the inputs affects the output of Model H-H2. To increase the variabilities of Model H-H2 output, the character vector (all of its elements

location 1	location 2	location 3
location 4	location 5	location 6
location 7	location 8	location 9

Figure 10: Location Assignment in the Character Matrix

are positive before the process) is modified according to the following rules:

```

do i=1 to 14 by 1
  if threshold[i]=0 then
    if C[i]=0 then
      C[i]=-4
    else
      C[i]=C[i]
    else
      C[i]=C[i]-threshold[i]
end i.

```

where threshold = [7 7 4 4 0 0 0 0 0 0 0 0 0 4].

The values of the threshold vector were chosen according to the frequency occurrence of the selected character properties for the 156 characters. The codes that go through the above processes are the inputs to the models.

Application of Models Through Simulation

During these simulations, the training set was composed of the vector representations of 78 characters: three out of the six fonts for each letter of the alphabet were randomly selected. All of the 156 character were the candidates for the recognition set.

For Model H-H1, the training set was fed to the model, repeatedly, during the training phase. The model computed the outputs and adjusted the memory matrix values, according

to its output function and the learning rule until there was convergence. After the model stabilized, the memory matrix values were fixed and the official outputs were generated by running the model one more time, using the training set. The model recorded the outputs as well as their associated letters. Thus the inputs were divided into several categories. In general, several letters fell into the same categories. This happened when more than two letters created the same output. Figure 11 shows an example of the decision tree. In this example, character E and character F produced the same output. The learning process was started again to create a child model using the vector representations of E's and F's as inputs. Another memory matrix was created to distinguish E's from F's. This process continued recursively, to build the decision tree until either each output was associated with only one letter or the depth of the tree reached 7. The depth of the decision tree was limited to 6 to avoid having the learning process run endlessly.

For Model H-H2, three characters (three fonts for the same letter) of the training set were submitted to the model at one time. The model computed the outputs and adjusted the memory matrix values based on the output function and coalescence rule described in Chapter II. After Model H-H2 converged, three vectors that represented another letter were sent to the model and the previous process was started

Figure 11: An Example of the Decision Tree

over again. After all of the 78 characters were learned, the values of the memory matrix were fixed. The training set was submitted to the model to obtain the official outputs. The model recorded the outputs as well as their associated letters. Normally, the model divided the inputs into several categories with those that produced the same output in one category. If two or more letters fell into the same category, the vector representations for those letters were again submitted to the model. The child model was created to discriminate the different letters that fell into one category by adopting the dissociation rule. These processes were run recursively to build the decision tree until either each output was associated with only one letter or the depth of the tree reached 7. When building the decision tree, the coalescence rule and the dissociation rule were used alternatively, with the odd depth for the coalescence rule and the even depth for the dissociation rule. Again, the depth of the decision tree was limited to 6 to prevent the process from running forever.

In the recognition process, all 156 codes were input to the models. The recognition set was submitted to the memory matrix in the root of the decision tree. If the output matched one of the outputs previously recorded and the output was only associated with one letter, then the model indicated that the input was the recorded character. On the other hand, if the output matched one of the outputs but

more than two letters were associated with it, the input code was sent to its child memory matrix for further process. The searching started from the root of the tree, and it stopped either when the memory matrix was a leaf node or the output did not match any of the outputs.

As a result, the simulation programs generated the following information:

1. overall recognition rate,
2. number of rejected characters,
3. number of correctly recognized characters,
4. recognition rate of the trained characters,
5. rejection rate of the trained characters,
6. recognition rate of the untrained characters,
7. rejection rate of the untrained characters,
8. depth of the decision tree,
9. number of the memory matrix used in the decision tree,
10. learning speed (in terms of number of iterations),
11. recognition speed (in terms of number of times),
12. number of correctly recognized characters for each alphabet,
13. number of rejected characters for each alphabet,
14. number of correctly recognized characters for each font, and
15. number of rejected characters for each font.

Model Comparisons

The parameters, such as memory matrix size, S_{min_Smax} , M_{min_Mmax} , were manipulated to determine the models' performance. The memory matrix sizes were set to be 4x14, 6x14, 8x14, and 10x14. S_{min_Smax} were assigned to be ± 12 , ± 15 , and ± 18 . For H-H1, M_{max} was set to be 4, 6, and 8 with M_{min} fixed to 1; for Model H-H2, M_{min_Mmax} was set to be ± 8 , ± 10 , and ± 12 . Thus 36 observations were obtained for each model. These levels were determined by expanding the levels used by Hogg and Huberman (1985). Table 2 presents the levels of parameters.

The performances of these models were determined using the following criteria: accuracy, required memory space, learning speed, and recognition speed. These four criteria are defined below

(1) The accuracy is scored as the fraction of correctly recognized characters with respect to the 156 characters.

(2) The required memory space is defined by the number of memory matrices used to build the decision tree. The less discriminative the model is, the more memory matrices are needed to build the tree. Generally speaking, the number of memory matrices required depends on the shape of the tree.

(3) The learning speed is determined by the number of iterations required to build the decision tree. The fewer

Table 2
Levels of Parameters

Model	Parameter	Levels			
		1	2	3	4
H-H1	Memory Matrix Size	4x14	6x14	8x14	10x14
	Smin_Smax	+12	+15	+18	
	Mmin_Mmax	1_4	1_6	1_8	
H-H2	Memory Matrix Size	4x14	6x14	8x14	10x14
	Smin_Smax	+12	+15	+18	
	Mmin_Mmax	+8	+10	+12	

iterations the model needs in the learning phase, the faster the learning speed is.

(4) The recognition speed is determined by the number of times the input data have to be submitted to the memory matrices in the decision tree in order to recognize 156 characters. The fewer the number of times the input data need to be submitted, the faster the recognition speed is. The recognition speed depends on the shape of the decision tree. Normally, the shallower the tree is, the faster the recognition speed is.

CHAPTER IV

SIMULATION RESULTS

To analyze the performances of the models, Statistics Analysis System, a computer system of software products for data analysis, was used. Basically, descriptive statistics (mean and standard deviation: STD) were obtained for performance data for each model. The effects of model parameters on model performance were determined statistically using an ANalysis Of VAriance (ANOVA) procedure. The performance comparison was conducted by Pairwised T Test.

In the first section, the extracted properties of the input characters are summarized. The principal component analysis of the character vectors is presented in the second section. The behavior of models as functions of the size of memory array, Smin_Smax, and Mmin_Mmax are presented in the third and fourth sections, respectively. Finally, model comparisons are discussed in the last section.

Characteristics of Collected Characters

Recall that 156 machine-printed characters were created for determinating the recognition performances of the models and fourteen selected properties were extracted from each

character. Figure 12 presents the frequency occurrence of the properties of the 156 letters. The property occurrence ranges from 7 for "cross," which is 0.16% of the total number of occurrence, to 1754 for "vertical line", which is over 40.44% of the total number of occurrence.

Principal Component Analysis

The dimensionality of the data can be reduced by removing or combining highly correlated data (Duda and Hart, 1973). Principal component analysis was used to reduce the dimensionality by forming linear combinations of character vectors features. SAS was used for this purpose. Table 3 illustrates the statistical result.

The eigenvalues indicate that nine components, which account for 92.55% of the standardized variance, provide a good summary of the data. The eigenvectors provide the principals as the linear combinations of the fourteen elements in the character vectors. The results of the computer simulations show that the recognition rate is lower when using the nine principals as the inputs than when using the 1x14 vector as the input code. The results also show that it requires more memory space and that the learning and recognition speeds are much slower. As a result, only 1x14 vectors were used as the input data to the models in this study. The performance data are presented in Table 4.

Behavior of Model H-H1

When observing the output patterns of Model H-H1, it can be seen that each element of the output vector is affected by half of the elements in the input vector. For example, the output element O_5 is a function of the input elements $I_1, I_3, I_5, I_7,$ and I_9 . Figure 13 illustrates this behavior.

For the purpose of illustration, an example of the program output from Model H-H1, where the size of the memory matrix was 8×14 , S_{min} was -15 , S_{max} was 15 , M_{min} was 1 , and M_{max} was 4 , is presented in Table 5. In this example, 78 letters (three fonts for each alphabetic character) were submitted to the model as the training set and all 156 letters were used as the testing data. As Table 5 indicates, the overall recognition rate was 84%. The recognition rate for the 78 trained letters was 100%, and 68% for the untrained letters. The depth of the recognition tree was 2. There were 6, 8×14 memory matrices in the tree. The learning speed was 492 iterations and the recognition speed was 186. The output also shows the number of correctly recognized letters and the number of rejected letters for each letter and for each font.

A total of 36 sets of computer output were generated from Model H-H1, using the following model parameters: (1) memory matrix sizes used were 4×14 , 6×14 , 8×14 , and 10×14 ; (2) S_{min} S_{max} values of ± 12 , ± 15 , and ± 18 were used; and (3)

the Mmax values were 4, 6, and 8 and Mmin was fixed at 1. Table 6 lists the resulting recognition rates, the number of memory matrices used, the learning speeds, and the recognition speeds.

Across all variables, the mean recognition rate was 82.15% (STD=2.31%); it ranged from 77.56% to 87.82%. On the average, 12.86 memory matrices were needed in the learning phase; the number ranged from 2 to 23. The mean learning speed was 707.14 (STD=215.79) iterations with the highest speed at 258 iterations and the speed at 1143 iterations. As for recognition speed, the mean was 216 (STD=26.15) and the range was 161 to 263. Overall, the program averaged 5.385 seconds of CPU time on the VAX 8650.

The ANOVA procedures were used to analyze the effects of varying the parameter levels on the performances of the models. Table 7 illustrates the ANOVA results. In this analysis, the dependent variables are recognition rate, memory space used, learning speed, and recognition speed. The independent variables were memory matrix size, Smin_Smax, and Mmin_Mmax.

Most of the variation in recognition rate was explained by the variable Mmin_Mmax (Table 7 (a)). The classifications of memory size and Smin_Smax made little contribution. A total of 32.68% of the variations were explained by these three variables. The Least Significant Difference (LSD) test showed no statistical difference in

recognition rate as a result of using the four memory matrix sizes and the three $S_{min_S_{max}}$ values. The third level of M_{max} , which was 8 (mean=83.54%), has a statistically higher recognition rate when compared to M_{max} equal to 4 (mean=81.20%) and 6 (mean=81.72%). This behavior suggests that the value of M_{max} may have a significant impact on the recognition rate. Figure 14 illustrates the recognition rate as a function of memory matrix size, $S_{min_S_{max}}$, and $M_{min_M_{max}}$, respectively.

Table 7 (b) shows that memory matrix sizes, $S_{min_S_{max}}$, and M_{max} can account for a 74.28% (R-Square) variation in memory space used by this model. Most of the variation was explained by the variable memory size; $S_{min_S_{max}}$ and M_{max} had little influence on the number of memory matrices needed. The LSD test showed that as the memory matrix size increased, the model needed more memory matrices to learn the letters. In other words, the larger the memory matrix was, the less discriminating the model was. For the 8x14 and the 10x14 memory matrix sizes, the mean number of memory matrices needed was 17.44; for the 6x18 memory size, the mean was mean was 10.89; for the 4x14 memory size, only 5.67 memory matrices were needed. The different values of $S_{min_S_{max}}$ did not make a statistically significant difference in the number of memory matrices needed. The larger the value of M_{max} was, the more memory matrices were needed. This suggests that the larger the value of M_{max} ,

Figure 14: Recognition Rate as a Function of Memory Matrix Size, Smin_Smax, and Mmin_Mmax (Model H-H1)

the less discriminating the model was. Figure 15 shows the memory space as a function of memory matrix size, S_{min_Smax} , and M_{min_Mmax} , respectively.

The statistical results show that 81.09% of the variation in learning speed was accounted for by the variations in memory matrix size, S_{min_Smax} , and M_{max} (Table 7 (c)). Memory matrix size and the value of M_{max} explained most of the variations in learning speed. As the memory matrix size increased, more iterations were needed in the learning phase. In other words, it took more time to build the decision tree. Also, the larger the magnitude of S_{min_Smax} , the slower the learning speed was. This was due to the fact that the larger the magnitude of S_{min_Smax} , the larger the range to be adjusted. By the same token, the larger the value of M_{max} was, the slower the learning speed was. Figure 16 illustrates the learning speed as a function of memory matrix size, S_{min_Smax} , and M_{min_Mmax} , respectively.

For the recognition speed, 69.31% of the variation was accounted for by the size of the memory matrix, S_{min_Smax} , and M_{max} value (Table 7 (d)). Of these three independent variables, the size of the memory matrix accounted for most of the variation. The LSD test showed that the larger the memory matrix size, the more times the input data needed to be submitted to the memory matrices during the recognition phase. This resulted in a slower recognition speed. It

Figure 15: Memory Space as a Function of Memory Matrix Size, Smin_Smax, and Mmin_Mmax (Model H-H1)

Figure 16: Learning Speed as a Function of Memory Matrix Size, Smin_Smax, and Mmin_Mmax (Model H-H1)

also showed that the larger the S_{min_Smax} , the slower the recognition speed. Figure 17 illustrates the recognition speed as a function of memory matrix size, S_{min_Smax} and M_{min_Mmax} , separately.

For comparison purposes, other computer simulations were conducted using all of the letters (156) as the training and the recognition set. Table 8 presents the 36 observations of Model H-H1 for recognition rate, memory space used, learning speed, and recognition speed. The mean recognition rate (STD= 2.59%) was 96.07% with a maximum of 100% and minimum of 89.1%. For number of memory matrices used, the mean was 37.17 (STD=25.75) and the range was from 8 to 104. The mean for learning speed was 2937 iterations (STD=1794.03) with the highest speed at 852 iterations and the lowest speed at 8148 iterations. The mean recognition speed was 255.86 (STD=40.11) times; the range was from 194 to 340 times.

Analysis of variance was used to analyze the data again. The result showed that the smallest memory matrix size (4x14) provided the highest recognition rate, the least number of memory matrices, the fastest learning speed, and the fastest recognition speed. This behavior was totally different from that when only three fonts were used in the training set.

Behavior of Model H-H2

Model H-H2 behaves in such a way that when the memory values are fixed to zeroes and there are no zero valued elements in the input vector, the output can be easily predicted without going through the computation. The behavior is demonstrated in Figure 18. Since the output values are saturated very fast (it takes $\log_2(S_{\max})$ rows to saturate), the magnitudes of the output elements are the same as S_{\max} . Their signs are determined by the size of the memory matrix and the signs of the input elements. To be specific, when the memory matrix contains an even number of rows, each output element has the same sign as its corresponding input element and a magnitude equal to S_{\max} ; when the matrix has an odd number rows, the signs of the output elements are the result of the right-shift of the signs of their corresponding input elements.

The output from program for Model H-H2 provided the same information as the output from Model H-H1. Table 9 presents an example of the program output, when the size of the memory matrix was 8×14 , S_{\min} was -15, S_{\max} was 15, M_{\min} was -10, and M_{\max} was 10. In this example, the overall recognition rate was 86% of the recognition set. The recognition rate for the 78 training letters was 100%, and the recognition rate for the other letters was 72%. The depth of the decision tree was 6 and there were 34, 8×14 memory matrices in the tree. The learning speed was 1211

iterations and recognition speed was 355. The Table also shows the number of correctly recognized characters and rejected characters for each letter and for each font.

Thirty-six sets of computer output were generated using Model H-H2, using the following values for the three variables. The sizes of the memory matrix were 4x14, 6x14, 8x14, and 10x14; Smin_Smax took on values of ± 12 , ± 15 , and ± 18 ; and Mmin_Mmax was set equal to ± 8 , ± 10 , and ± 12 . Again the performance of the model was measured by recognition rate, memory space needed, learning speed, and recognition speed. Table 10 lists the results.

Overall, the mean recognition rate was 83.67% (STD=4.17%) of the recognition set. It ranged from 72.43% to 89.10%. On average, 13.17 memory matrices were needed in the learning phase; this ranged from 4 to 29. The mean learning speed was 654.81 (STD=255.75) iterations with the highest speed at 316 iterations and the lowest speed at 1418 iterations. For recognition speed, the mean was 283.67 times (STD=38.46); it ranged from 194 to 346. The average CPU time was 6.47 seconds for Model H-H2 to complete the recognition process on the VAX 8650.

Table 11 illustrates the results of an analysis of variance of recognition rate, memory space used, learning speed, and recognition speed, respectively. According to the statistical analysis, 66.23% of the variations of recognition rate were accounted for by the three independent

Mmin_Mmax	2	6765.5000	6.33	0.0054

variables (Table 11 (a)). Most of the variation in recognition rate was explained by memory matrix size. The classifications of S_{min_Smax} and M_{min_Mmax} made little contribution. The LSD test indicated that the recognition rate was (86.68%) higher when the memory size was 8x14 or 10x14 compared to 82.69% and 78.99% with memory matrix sizes of 6x14 and 4x14. On the other hand, the LSD test showed no statistical difference among the three levels of S_{min_Smax} values and the three levels of M_{min_Mmax} values in terms of recognition rate. Figure 19 illustrates the recognition rate as a function of memory matrix size, S_{min_Smin} , and M_{min_Mmax} , respectively.

Table 11 (b) shows that memory matrix sizes, S_{min_Smax} , and M_{max} can account for only 42.97% (R-Square) of the variation in memory space used in this model. Most of the variation was explained by the memory matrix size. S_{min_Smax} and M_{max} had little influence on the number of memory matrices needed. The LSD test showed that as the memory matrix size increased, the number of memory matrices used in the learning phase increased with statistical significance. With a memory size of 4x14, the mean number of memory matrices used was only 7.11; with a 10x14 memory matrix, the mean number of memory matrices used increased to 19.78. In other words, the larger the memory matrix was, the less discriminating the model was. The different values of S_{min_Smax} and M_{min_Mmax} made no statistically significant

Figure 19: Recognition Rate as a Function of Memory Matrix Size, Smin_Smax, and Mmin_Mmax (Model H-H2)

difference in terms of number of memory matrix needed. Figure 20 illustrates the memory space as a function of memory matrix size, S_{min_Smax} , and M_{min_Mmax} , separately.

The statistical analysis showed that 58.21% of the variation in learning speed could be accounted for by memory matrix size, S_{min_Smax} , and M_{min_Mmax} (Table 11 (c)). Memory matrix size explained most of the variation in the learning speed; the different values of S_{min_Smax} and M_{min_Mmax} made small contributions. The result of the LSD test showed that as the memory matrix size increased more iterations were needed. It took more time to build the decision tree. The levels of S_{min_Smax} and M_{min_Mmax} make no statistically significant difference in the learning speed. Figure 21 illustrates the learning speed as a function of memory matrix size, S_{min_Smax} and M_{min_Mmax} , respectively.

As far as recognition speed was concerned, the greater the number of times needed to recognize the letters, the slower the recognition speed was. The result indicated that 71.11% of the variations in recognition speed were explained by the various sizes of the memory matrix, S_{min_Smax} , and M_{min_Mmax} values (Table 11 (d)). Of these three independent variables, the size of the memory matrix contributed most to the explanation of the variation. The LSD test showed that the larger the memory matrix size, the more times were needed. For the 4x14 memory matrix size, it only took

Figure 20: Memory Space as a Function of Memory Matrix Size, Smin_Smax, and Mmin_Mmax (Model H-H2)

Figure 21: Learning Speed as a Function of Memory Matrix Size, Smin_Smax, and Mmin_Mmax (Model H-H2)

236.44 (on average) times to recognize 156 letters; whereas with 8x14 memory matrix size, it took 309.11 times. It also showed that the larger the magnitude value of M_{min_Mmax} was, the slower the recognition speed was. Figure 22 illustrates the recognition speed as a function of memory matrix size, S_{min_Smax} and M_{min_Mmax} , separately.

Table 12 presents the 36 observations of Model H-H2 for recognition rate, memory space used, learning speed, and recognition speed, when all 156 characters were submitted as both the training set and the recognition set. The mean recognition rate was 99.41% (STD=7.24%) with the highest at 100% and lowest at 96.15%. This suggested that learning was perfect only for some parameter combinations. For number of memory matrices used, the mean was 19.11 (STD=8.61); it ranged from 5 to 38. The mean for learning speed was 1285.78 iterations (STD=424.38) with the highest speed at 715 iterations and the lowest speed at 2090 iterations. The mean recognition speed was 309.11 (STD=42.96) times and ranged from 178 to 382.

Analysis of variance was used to analyze the data again. Among all memory matrix sizes, the smallest memory matrix size (4x14) provided the highest recognition rate, the least number of memory matrices needed, and the fastest learning and recognition speeds. This behavior is totally different from the behavior when only three fonts were used as the training set.

Model Comparisons

Model H-H1 versus Model H-H2

To distinguish the performance differences between Model H-H1 and Model H-H2, the Pairwised Comparison Test (Pairwised T Test) was conducted. Table 13 lists the performance differences between Model H-H1 and Model H-H2 when using three out of six fonts as the training set. Table 14 presents the test results.

The Pairwised T Test indicated that only the recognition speed had a statistically significant difference when models H-H1 and H-H2 were subjected to the experimental variables in the study. The sign of the mean score indicated that Model H-H2 required more time during the recognition phase. The test results failed to justify statistically that there was any difference in recognition rate, memory space, and learning speed between the two models. In spite of that, Model H-H1 had a lower mean recognition rate and a slower mean learning speed. Model H-H1 required less mean memory space and provided a faster mean recognition speed.

On the other hand, the two models behaved significantly different under when six fonts were used as both the training set and the recognition set. Table 15 lists these performance differences.

The Pairwised T Test (Table 16) illustrated that the performance data of the two models had a statistically

significant difference. The recognition rate of Model H-H2 was significantly higher (3.34% higher) than that of Model H-H1. For the number of memory matrices used, Model H-H1 required many more matrices than Model H-H2. As Table 16 shows, on the average, Model H-H1 required 37.17 memory matrices which was 18.08 more than Model H-H2. Also, the learning speed of Model H-H1 was much slower than that of Model H-H2. Model H-H1 required 2937 iterations which was 1651.63 more than Model H-H2 in the training phase. As far as the recognition speed was concerned, Model H-H1 performed much faster than Model H-H2 did. On average, the input data had to be submitted 309.11 times in Model H-H1 which was 53.25 more times than in Model H-H2 in the recognition phase. In conclusion, Model H-H2 outperformed Model H-H1 in terms of recognition rate, memory space used, and learning speed when 156 characters were used as the training set.

Hogg and Huberman versus Cash and Hatamian

The recognition rates of models H-H1 and H-H2 were compared to the result of Cash and Hatamian's study (1987). In this study, both H-H1 and H-H2 performed better, in terms of recognition rate, than the optical character recognition using the method of moments (Cash and Hatamian, 1987). In their study, the training and recognition sets are both six machine-printed fonts in alphanumeric characters. The six

fonts used in their study were Courier, Elite, Pica, Helvetica, Memphis Medium, and Times Bold Italic. In the training phase, the training documents were isolated by contour tracing, and then the 2D moments of each character were computed and stored in a library of feature vectors. In the recognition phase, the document to be recognized was scanned, and the 2D moments of its characters were compared with those in the library for classification. They claimed that recognition rates between 98.5% and 99.7% have been achieved for all fonts test. However, The Hogg and Huberman models (Model H-H1 and Model H-H2) have 100% recognition rate for some parameter combinations (e.g., 4x14 memory matrix size, $S_{min_Smax}=\pm 18$, $M_{min}=1$, and $M_{max}=4$ for Model H-H1; 4x14 memory matrix size, $S_{min_Smax}=\pm 18$, and $M_{min_Mmax}=\pm 8$ for Model H-H2). Clearly, the performance of models H-H1 and H-H2 are significantly better. This comparison was made when all of the recognition set was used as the training set, as was the case in Cash and Hatamian's study.

Hogg and Huberman versus Fujii and Morita

When comparing the performance of Model H-H1 and Model H-H2 to the performance of the recognition system using a similar encoding scheme, the Hogg and Huberman models outperformed the Fujii and Morita's study (1971). Fujii and Morita used a simulation of the visual nervous system as

their recognition system. In their study, a cascade connection of the lateral inhibition structure and the Adaline learning system were applied to the handwritten recognition problem. Both the training and the recognition sets were handwritten numerals (0-9). Eleven properties were extracted from each of the handwritten letters. Then the adaptive classifier was trained with supervision. In the training phase, the training set (400 numerals) were submitted to the classifier and the connection weights in the classifier were adjusted accordingly. One hundred suitably selected characters from the training set were submitted to the classifier in the recognition phase. Fujii and Morita claimed that the 100 suitably selected characters were identified 100% correctly. On the other hand, models H-H1 and H-H2 have achieved 100% accurate recognition for all the training data. This indicates that the Hogg and Huberman models are more appropriate than the system that was based on the simulation of the visual nervous system for the font recognition application.

CHAPTER V
CONCLUSIONS AND RECOMMENDATIONS
FOR FUTURE RESEARCH

Conclusions

Two neural network models have been successfully applied to the font recognition problem. The models used were developed by Hogg and Huberman (1984, 1985) and were used in this research to recognize the 26 capitalized English letters, each with six font representations. Recognition rate, memory space used, learning speed, and recognition speed were used to measure models' performances. Model parameters such as memory array size, Smin_Smax, and Mmin_Mmax were varied to elucidate the models' behaviors. To interpret the results of this study, it is important to consider the validity and sensitivity of these models. The conclusion of this study are as follows:

(1) The Hogg and Huberman models (Model H-H1 and Model H-H2) are useful in font recognition. Both models achieved a 100% recognition rate for particular parameter combinations (e.g., 4x14 memory matrix size, Smin_Smax =+18, Mmin=1, and Mmax=4 for Model H-H1; 4x14 memory matrix size, Smin_Smax =+18, and Mmin_Mmax =+8 for

Model H-H2) when all six fonts were submitted as both the training and the recognition set.

(2) Recognition is better, when using these models, than any previous models for this problem, the comparisons are: (a) The recognition performance of these two models are considerably better than the character recognition method using moments (Cash and Hatamian, 1987). Model H-H1 and Model H-H2 achieved a perfectly accurate recognition performance; while Cash and Hatamian's research achieved only a 98.5% to 99.7% recognition rate. (b) Models H-H1 and H-H2 outperformed the recognition system of Fujii and Morita (1971). The encoding scheme used in this study was similar to the encoding scheme used in their study. Although a 100% recognition rate was obtained in their study, their testing data consisted of only 1/4 of the training data and only numerals were recognized in their research. In this study, when there were twice as many fonts in the recognition set as they were in the training set, the highest recognition rate was 87.82% for Model H-H1 and 89.10% for Model H-H2. When all the training sets (six fonts) were submitted as the recognition set, the highest recognition rate was 100.00% for both models. This indicates that the Hogg and Huberman models are better recognition algorithms than the simulated visual nervous recognition system used by Fujii and Morita.

(3) Model H-H2 significantly outperformed Model H-H1 in terms of recognition rate, use of memory space, and learning speed when the models trained all six fonts for the 26 English letters. This was supported by the results of the Pairwise T Test. However, the test results showed that Model H-H2 required more time to recognize the recognition set than Model H-H1 did.

(4) The recognition rate for fonts that were not in the training set was also acceptable. Other models did not test fonts that are not trained. When three out of six fonts were used for training, Model H-H1 achieved a maximum recognition rate 87.82% and Model H-H2 achieved a maximum recognition rate 89.10%. This indicates that the models were capable of recognizing some of the untrained characters. This behavior shows that the basins of attractor states existed for the letters in most of the various font presentations.

(5) The Hogg and Huberman models can be useful in other pattern recognition problems. The fonts used in this study certainly represent a pattern class. Since Model H-H1 and Model H-H2 can achieve reliable font recognition, it seems that they should be able to exhibit highly accurate recognition behavior in other pattern recognition problems.

Recommendations for Future Research

This study applied the Hogg and Huberman models to the font recognition problem and it has prepared a foundation for further research in these areas:

(1) This work only investigated the line characters (i.e., characters that are only one unit wide). Most fonts have a width larger than 1 for various parts of the letters. More work needs to be done to see if the excellent results achieved here can be extended to more realistic fonts. The lower case English letters, numerals, and handwritten letters also should be investigated.

(2) Further improvement of model performance for the untrained fonts should be attempted by increasing the number of character properties and/or by selecting different character properties.

(3) Further research on how the performance is affected by the introduction of degraded or corrupted letters should also be investigated prior to committing to a system design.

(4) A hardware implementation of the models appears feasible since a reliable recognition performance (100% recognition rate) has been achieved. According to the study done by McClain, Rogers, and Oldham in 1988, the inherent parallelism operations in the models gives them a definite speed advantage over conventional sequential computers. In their study, they claimed that the performance of the Hogg and Huberman model (Model H-H1) can gain in excess of 400

times using two GAPP chips versus the VAX (11/780). The CPU time for running Model H-H1 to train 156 characters and to recognize 156 characters was 4.5 seconds, when the memory matrix size was 4x6, $S_{min_Smax}=\pm 18$, $M_{min}=1$, and $M_{max}=4$. Using the results of McClain, et al., it should take only 11.2 millisecond to train and recognize 156 characters if Model H-H1 is implemented in hardware. Because the learning speed versus recognition speed was 852:194, it should take less than 2.08 milliseconds to recognize 156 characters. Assume that an envelope has 100 characters on it (all English capital letters), it would cost only 1.33 milliseconds to recognize the characters on the envelope. This suggests that the hardware implementation of the Hogg and Huberman models can provide satisfactory speed and can be used as a character recognition device in post offices.
